³Department of Agronomy, Faculty of Agriculture, Cairo University, Egypt.

T wo field experiments were conducted at a private field in Qalin City, Kafr El sheikh Governorate, Egypt, during 2021/2022 and 2022/2023 seasons to study the response productivity and grain quality of some wheat cultivars (Sakha 95 and Misr-3) to seeding rates (30, 50 and 70 kg grains fed⁻¹) and nitrogen levels (50, 75 and 100 kg N fed⁻¹) under different sowing dates (25th Oct., 25th Nov. and 25th Dec.). Each sowing date was performed in separate experiment. Every experiment of sowing dates was carried out in split- split plot design with four replications. The main-plots were assigned to new Egyptian wheat cultivars. While, the sub-plots were randomly allocated to seeding rates. Whilst, the sub-sub plots were randomly distributed to nitrogen fertilizer levels. The obtained results revealed that the studied seasons, sowing dates, wheat cultivars, seeding rates and nitrogen fertilizer levels significantly affected No. of spikes m⁻², spike length, No. of spikelets spike⁻¹, No. of grains spike⁻¹, 1000-grain weight, biological and grain yields fed⁻¹, harvest index (HI) and crude protein percentage in most cases. From the achieved results of this study, it could be recommended that sowing wheat Sakha 95 cultivar on 25th November with 50 kg grains fed⁻¹and fertilizing with 100 kg N fed⁻¹to obtain the highest productivity and grains quality under the environmental conditions of Qalin City, Kafrelsheikh Governorate, Egypt.

Keywords: Wheat, sowing dates, cultivars, seeding rates, nitrogen levels, productivity, grain quality.

Introduction

Wheat (Triticum aestivum L.) is globally the major source of food for human nutrition after rice and maize and a part of daily dietary need in one form or more. It is the main winter cereal crop and an important staple food crop in Egypt. Wheat is the most widely grown crop in the world with its unique protein characteristics and serves as an important source of food and energy (Abedi et al., 2010). It is easily processed into various types of food like bread, macaroni, biscuit and sweets. During 2021/2022 season in Egypt, wheat crop was grown on an area of 3.404 million feddan (one feddan = 4200 m^2) with an annual production of 9.700 million tons and average yield of 18.997 ardab (one ardab = 150 kg) per feddan (FAO, 2023).

Sowing date plays an important role in determining wheat productivity, where the final grain yield depended on the time of sowing. Jagjot *et al.* (2018) found that maximum plant height, effective tillers m^{-2} , spike length, grains No. per spike, 1000-grain weight and highest grain yield were attained by the

crop planted on 10th Nov. Kalwar *et al.* (2018) recommended that farmers should complete their cultivation of wheat crop in first half of November to get more yield and financial benefits.

Chosen the high yielding ability cultivars undoubtedly is very important to raise wheat productivity per unit area (El-Hag, 2019). The wheat cultivars Sakha 95 and Misr-3 are the new cultivars for high quality bread in Egypt, with the little research indicating suitable sowing dates, seeding rates and nitrogen fertilizer levels.

The seeding rate (plant density) is one of the more important requirements in agronomic planting for achieving high yield with optimal quality. Seeding rate, wheat several researchers suggested positive effect of seeding rates on growth, yield components, yields and grain quality (Yang *et al.*, 2019). Ahmad *et al.* (2018) concluded that seed rate of 115 kg ha⁻¹ produced maximum grain yield of wheat.

Nitrogen is often the most deficient of all the plant nutrients. Wheat is susceptible to insufficient nitrogen and very responsive to nitrogen fertilization. It is crucial for plant growth and final

*Corresponding author email:emad.rashwan@agr.tanta.edu.eg Received 21/1 /2024 ; Accepted 26/5 /2024 DOI: 10.21608/agro.2024.264453.1410 ©2024 National Information and Documentation Center (NIDOC) grain yield of wheat, and it should be applied at the optimum rate to meet the crop need. Several authors studied the response of wheat to nitrogen fertilizer. Gharib *et al.* (2016) and Kousar *et al.* (2015) found that increasing nitrogen levels from 0 up to 150 significantly increased the fertile tillers, plant height, spike length, No. of grains per spike, 1000 grain weight, grain yield per plot, and grain yield kg ha⁻¹. Khaled and El-rawy (2012) recommended that increasing nitrogen levels from 0 up to 105 kg N fed⁻¹ led to rising of dry matter, LAI, plant height, No. of grains spike⁻¹, No. of spikes No. of spikes m⁻², 1000-grain weight, grain yield, straw yield, and grain protein %.

Thus, the present study was conducted to determine the response productivity and grain quality of some wheat cultivars to seeding rates and nitrogen levels under different sowing dates under the environmental conditions of Qalin City, Kafrelsheikh Governorate, Egypt.

Materials and Methods:

Two field experiments were conducted at a private field in Qalin City, KafrElsheikh Governorate, Egypt, (the site was located at 25.21° N, 28.51°E and 125 m level above sea level) during 2021/2022 and 2022/2023 winter seasons.

Each sowing date was performed as a separate experiment *i.e.* three experiments $(25^{\text{th}} \text{ Oct.}, 25^{\text{th}} \text{ Nov.} \text{ and } 25^{\text{th}} \text{ Dec.})$. Every experiment of sowing dates was carried out in split- split plot design with four replications. The main-plots were assigned to two new Egyptian wheat cultivars (Sakha 95 and Misr-3). While, the sub-plots were randomly allocated to three seeding rates (30, 50 and 70 kg grains fed⁻¹). The sub-sub plots were randomly distributed to nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹). Nitrogen fertilizer in the form of urea (46.5 % N) was applied in two equal doses. The first dose was added before the first irrigation and the other was added before the second irrigation.

Each experimental unit was 2×2.1 m occupying an area of 4.2 m² and each plot included ten rows with 50 cm between plots. The preceding summer crop was rice (*Oryza sativa* L.) in both seasons.

Random soil samples were taken from the experimental field at a depth of 0 - 30 cm from soil surface before soil preparation to measure the physical and chemical soil properties as described by Page (1982) as shown in Table 1.

both seasons.		-

Organic mat	ter (%)	1.50	1.55				
	Ν	18.00	20.00				
Available $(mg kg^{-1})$	Р	13.80	14.50				
	K	260.00	265.00				

The experimental field was well prepared through two ploughings, compaction, division and then divided into the experimental units with dimensions as previously mentioned. Phosphorus fertilizer in the form of calcium super phosphate (15.5 % P_2O_5) was applied during soil preparation at the rate of 200 kg fed⁻¹.

The cultivation of wheat was took place on the aforesaid studied sowing dates of the seeding rates by using broadcasting (a fir method). The first irrigation was applied at 25 days after sowing and then plants were irrigated every 21 days until the dough stage.

The potassium fertilizer in the form of potassium sulphate (48 % K_2O) was broadcasted at the rate of 50 kg fed⁻¹ in the first irrigation. Common agricultural practices for growing wheat according to the recommendations of Ministry of Agriculture, except the factors under study.

At harvesting, one square meter was randomly selected from each plot to estimate the following yield components; No. of spikes m-², spike length (cm), No. of spikelets spike⁻¹, No. of grains spike⁻¹ and 1000 – grains weight (g).

Biological yield (ton fed⁻¹) was calculated by harvesting whole plants in each plot and air dried and weighted (kg plot⁻¹), which was converted to

ton per feddan. Grain yield (ardab fed⁻¹) was calculated by harvesting whole plants in each plot and air dried, then threshed and the grains at 13 % moisture were weighted in kg and converted to ardab per feddan (one ardab = 150 kg). Harvest index (HI) was calculated by using the following equation:

Harvest index (HI) = $\frac{\text{Grain yield (ardab fed} - 1)}{\text{Biological yield (ton fed} - 1)}$

Total nitrogen in wheat grains was estimated by the improved Kjeldahl – method according to A.O.A.C. (2007). Crude protein percentage as grain quality was calculated by multiplying the total nitrogen values in wheat flour by 5.75.

All obtained data were statistically analyzed by analysis of variance (ANOVA) for the split-split plot design to each experiment (sowing dates), then combined analysis was done among sowing dates experiment as published by Gomez and Gomez (1984) by using "MSTAT-C" computer software package. Bartlett's test was done to test the homogeneity of variances error. Means of the treatments were compared using Duncan's multiple range tests at 5 % level of probability as described by Duncan (1955).

Results and Discussion:

Effects of cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons: 1. No. of spikes m⁻²:

The results in Table 2 indicate that No. of spikes m² significantly differed due to various studied cultivars (Sakha 95 "C₁" and Misr-3 "C₂") under three studied sowing dates in both seasons. Where, C₂ cultivar surpassed other studied cultivar and resulted in the highest No. of spikes m⁻² under three studied sowing dates in both seasons. While, C₁ cultivar recorded the lowest No. of spikes m⁻² under three studied sowing dates in both seasons. The former results might be related to genetic factors make up by the used cultivars. These results are in conformity with those reported by Baqir and Al-Naqeeb (2018), Gomaa *et al.* (2018) and Hassanein *et al.* (2018)

Increasing seeding rates from 30 to 50 and 70 kg grains fed⁻¹ associated with significant increase in No. of spikes m⁻² under three studied sowing dates in both growing seasons (Table 2). The highest No. of spikes m⁻² produced from sowing with the highest seeding rate (70 kg grains fed⁻¹) under three studied sowing dates in both seasons. However, the lowest No. of spikes m⁻² were obtained from sowing with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. The increase in No. of spikes m⁻² due to increasing seeding rate might be ascribed to increase No. of plants, total tillers, non-effective tillers as well as No. of effective tillers that formed spikes per square meters. Comparable results were stated by Ahmad et al. (2018), Yang et al. (2019), Iqbal et al. (2020) and Matsuyama and Ookawa (2020).

 TABLE 2: Mean squares and mean performance of No. of spikes m⁻² as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

Data in Table 2 show that studied nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) had a significant effect on No. of spikes m⁻² under three studied sowing dates in both seasons. It was observed that application of 100 kg N fed⁻¹ resulted in the highest No. of spikes m⁻² under three studied sowing dates in both seasons. In contrast, the lowest No. of spikes m⁻² resulted from application of 50 kg N fed⁻¹ under three studied sowing dates in both seasons. Such increases in the No. of spikes per square meter as a result of increasing nitrogen fertilizer levels may be due to the roles of nitrogen in encouragement meristem division which increases plant ability to produce more tillers which give more spikes. Parallel results were obtained by Yang *et al.* (2019) and Seadh *et al.* (2020).

With respect to the interactions, the interaction between $C \times SR$ under three studied sowing dates in both seasons and the interaction between $C \times N$ in 25th November sowing date in the first season had a significant effect on No. of spikes m⁻², vice versa with regard to other interactions (Table 2).

2. Spike length (cm):

As shown from data in Table 3, there were significant differences among studied cultivars (Sakha 95 "C₁" and Misr-3 "C₂") in spike length in the first sowing date (25^{th} October "SD₁") in both seasons, while these differences were insignificant in both sowing dates on 25^{th} November (SD₂) and 25^{th} December (SD₃) in both seasons. The highest values of spike length were obtained from C₁ cultivar, which were 12.14 and 11.83 cm in the first and the second seasons, respectively. The variation among wheat cultivars in spike length may be due

to the genetical variation of them. Comparable results were obtained by Hassan *et al.* (2017).

Seeding rates of 30, 50 and 70 kg grains fed⁻¹ insignificantly affected spike length under three studied sowing dates in both seasons, except third sowing date (25th December) in both seasons as shown from data in Table 3. Sowing wheat plants with the lowest seeding rate (30 kg grains fed⁻¹) resulted in the highest values of spike length under three studied sowing dates in both seasons. Such increase in spike length as a result of decreasing seeding rate might be due to better interception and utilization of solar radiations and the increase in photosynthetic processes in case of lowest seeding rate, which led to an increase in all yield and its components. These results are coincidence with those obtained by Ahmad *et al.* (2018).

Data listed in Table 3 show that nitrogen fertilizer levels markedly affected spike length under three studied sowing dates in both seasons. Application of 100 kg N fed⁻¹ produced the highest values of spike length under three studied sowing dates in both seasons. In contrast, the lowest values of spike length under three studied sowing dates were resulted from application of 50 kg N fed⁻¹ in both seasons. This increase in spike length as a result of increasing nitrogen fertilizer levels may be recognized to the role of nitrogen in protoplasm and chlorophyll formation, enhancement meristematic activity and cell division, consequently increases cell size which caused increase in internodes length, accordingly increases in spike length. Analogous results were reported by Seadh et al. (2020).

 TABLE 3: Mean squares and mean performance of spike length as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

With concern to the interactions, the interactions among studied factors were insignificant under three studied sowing dates in both seasons, with exception the interaction between $C \times SR$ and the interaction between $C \times N$ in 25th November sowing date in the second season only (Table 3).

3. No. of spikelets spike⁻¹:

Wheat cultivars under study (Sakha 95 "C₁" and Misr-3 "C₂") were significantly differed in No. of spikelets spike⁻¹ under three studied sowing dates in both seasons as shown in Table 4. C₁ cultivar surpassed other studied cultivar and resulted in the highest No. of spikelets spike⁻¹ in the first sowing date in both seasons. While, C₂ cultivar recorded the highest No. of spikelets spike⁻¹ in the second and third sowing dates in both seasons. These results might be related to genetic factors and genetic makeup of the wheat studied cultivars.

Corresponding results listed in Table 4 which revealed that there was insignificant effect on No. of spikelets spike⁻¹ due to studied seeding rates (30, 50 and 70 kg grains fed⁻¹) under three studied sowing dates in both seasons, except third sowing date (25th December) in the first season. The highest No. of spikelets spike⁻¹ were recorded due to sow with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. On opposition to, the lowest No. of spikelets spike⁻¹ were produced from sowing with the highest seeding rate (70 kg grains fed⁻¹) under three studied sowing dates in both seasons. This increase in No. of spikelets spike⁻¹ due to decreasing seeding rate might have been due to the same reasons that mentioned and discussed in spike length. These results are in line with those reported Matsuyama Ookawa by and (2020).

Concerning the effect of nitrogen fertilizer levels on No. of spikelets spike⁻¹, the results indicated that No. of spikelets spike⁻¹ was significantly affected by nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) under three studied sowing dates in both seasons, except in the third sowing date (25th December "SD₁") in the second season (Table 4). Application of 100 kg N fed⁻¹ resulted in the highest No. of spikelets spike⁻¹, while application of 50 kg N fed⁻¹ resulted in the lowest No. of spikelets spike⁻¹ under three studied sowing dates in both seasons. Such increase in No. of spikelets spike⁻¹ as a result of increasing nitrogen fertilizer levels may be imputed to its effective role in enhancement spike length and nutritive status of wheat plant. Alike results were reported by Seadh *et al.* (2020).

No. of spikelets spike⁻¹ was insignificantly affected by various interactions among studied factors *i.e.* cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates in both seasons (Table 4).

4. No. of grains spike⁻¹:

The results in Table 5 indicate that No. of grains spike⁻¹ significantly differed due to various studied cultivars (Sakha 95 " C_1 " and Misr-3 " C_2 ") under three studied sowing dates in both seasons. Where,

 C_1 cultivar surpassed other studied cultivar and resulted in the highest No. of grains spike⁻¹ in the first and second sowing dates in both seasons. While, C_2 cultivar recorded the highest No. of grains spike⁻¹ in the third sowing date in both seasons. These results might be related to genetic factors and genetic makeup of the wheat studied cultivars. These results are in conformity with those reported by El-Sayed *et al.* (2018) and Gomaa *et al.* (2018).

Increasing seeding rates from 30 to 50 and 70 kg grains fed⁻¹ associated with significant decrease in No. of grains spike⁻¹ under three studied sowing dates in the first growing season, while these increases did not significant under three studied sowing dates in the second growing season (Table 5). The highest No. of grains spike⁻¹ produced from sowing with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. However, the lowest No. of grains spike⁻¹ were obtained from sowing with the highest seeding rate (70 kg grains fed⁻¹) under three studied

sowing dates in both seasons. The increase in No. of grains spike⁻¹ due to decreasing seeding rate might be ascribed to the same reasons that mentioned and discussed in spike length. Comparable results were stated by Iqbal *et al.* (2020) and Matsuyama and Ookawa (2020).

Data in Table 5 show that studied nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) had a significant effect on No. of grains spike⁻¹ under three studied sowing dates in both seasons. It was observed that application of 100 kg N fed⁻¹ resulted in the highest No. of grains spike⁻¹ under three studied sowing dates in both seasons. In contrast, the lowest No. of grains spike⁻¹ were resulted from application of 50 kg N fed⁻¹ under three studied sowing dates in both seasons. Such increase in No. of grains spike⁻¹ as a result of increasing nitrogen fertilizer levels may be imputed to its effective role in enhancement spike length, No. of spikelets spike⁻¹ and nutritive status of wheat plant in addition increasing flowers fertility. Parallel results were obtained by Yang et al. (2019) and Seadh et al. (2020).

 TABLE 5: Mean squares and mean performance of No. of grains spike⁻¹ as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

With respect to the interactions, the interaction between $C \times SR$ and $C \times N$ in 25th November sowing date in the first season and in 25th October sowing date in the second season, the interaction between $SR \times N$ in 25th December sowing date in the first season and the interaction between $C \times SR$ $\times N$ in 25th December sowing date in both seasons and in 25th December sowing date in the first season had a significant effect on No. of grains spike⁻¹, vice versa with regard to other interactions (Table 5).

5. 1000 – grain weight (g):

As shown from data in Table 6, there were significant differences among studied cultivars (Sakha 95 "C₁" and Misr-3 "C₂") in 1000-grain weight in the first and second sowing dates (SD₁" and SD₂) in the first season. The highest values of 1000-grain weight were obtained from C₁ cultivar, which were 33.53 and 34.24 g in the first and the second seasons, respectively. The variation among wheat cultivars in 1000-grain weight may be due to the genetical variation among them. Comparable

results were obtained by El-Sayed *et al.* (2018), Gomaa *et al.* (2018) and Hassanein *et al.* (2018). Seeding rates of 30, 50 and 70 kg grains fed⁻¹ insignificantly affected 1000-grain weight under three studied sowing dates in both seasons, except second and third sowing dates (25th November and 25th December) in the first season as shown from data in Table 6. Sowing wheat plants with the lowest seeding rate (30 kg grains fed⁻¹) resulted in the highest values of 1000-grain weight under three studied sowing dates in both seasons. These results may be due to the high competition between the adjacent plants at higher seeding rate for light, water and nutrients which led to decrease photosynthetic activities and produce less dry matter accumulated in different plant organs. These results are in well agreement with those obtained by Iqbal *et al.* (2020).

 TABLE 6: Mean squares and mean performance of 1000 – grain weight as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

Data listed in Table 6 show that nitrogen fertilizer levels markedly affected 1000-grain weight in the first sowing date (25th October "SD₁") in the first season and in the second sowing date (25th November "SD₂") in the second season. Application of 100 kg N fed⁻¹ produced the highest values of 1000-grain weight under three studied sowing dates in both seasons. In contrast, the lowest values of 1000-grain weight under three studied sowing dates were resulted from application of 50 kg N fed⁻¹ in both seasons. These increases in 1000 - grain weight due to increasing nitrogen fertilizer levels may be ascribed to its role in activating cells division, size, elongation, also metabolic and photosynthesis processes, and consequently increased grains weight. These results are in line with those reported by Seadh et al. (2020).

With concern to the interactions, the interactions among studied factors were insignificant under three studied sowing dates in both seasons, with exception the interaction between C \times SR in 25th December in the first season only (Table 6).

6. Biological yield (t fed⁻¹): Wheat cultivars under in this (Sakha 95 " C_1 " and Misr-3 " C_2 ") were

significantly differed in biological yield fed⁻¹ in the first sowing date in both seasons, but these differences in the second and third sowing dates in both seasons were insignificant as shown in (Table 7). C_1 cultivar surpassed other studied cultivars and resulted in the highest values of biological yield fed⁻¹ in the first sowing date in both seasons. While, C_2 cultivar recorded the highest values of biological yield fed⁻¹ in the second and third sowing dates in both seasons. These results might be related to genetic factors and genetic makeup of the wheat studied cultivars. These results are in agreement with those reported by Hassanein *et al.* (2018).

Corresponding results listed in Table 7 which revealed that there was insignificant effect on biological yield fed⁻¹ due to studied seeding rates (30, 50 and 70 kg grains fed⁻¹) under three studied sowing dates in both seasons, except the first sowing date (25th October) and the third sowing date (25th December) in the first season. The highest values of biological yield fed⁻¹ were recorded due to sow with the highest seeding rate (70 kg grains fed⁻¹) under three studied sowing dates in both seasons. On opposition to, the lowest

values were produced from sowing with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. This increase in biological yield fed⁻¹ due to decreasing seeding rate might have been due to the increase in No. of plants at harvest and high soil fertility.

Concerning the effect of nitrogen fertilizer levels on biological yield fed⁻¹ of wheat, the results indicated that biological yield fed⁻¹ was significantly affected by nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) under three studied sowing dates in both seasons, except the second sowing date (25^{th})

November "SD₂") in both seasons (Table 7). Application of 100 kg N fed⁻¹ resulted in the highest values of biological yield fed⁻¹, while application of 50 kg N fed⁻¹ resulted in the lowest values of biological yield fed⁻¹ of wheat under three studied sowing dates in both seasons. The increase in biological yield fed⁻¹ as a result of increasing nitrogen fertilizer levels might be related to the role of nitrogen fertilizer in improving vegetative growth, plant height and stem diameter accordingly increasing biological yield per unit area.

 TABLE 7: Mean squares and mean performance of biological yield fed⁻¹ as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

The authors thank the members of the plant virus Biological yield fed⁻¹ was insignificantly affected by various interactions among studied factors *i.e.* cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates in both seasons, except the interaction between C × SR in the first sowing date (25th October) in the two growing seasons and the interaction between C × N in the first sowing date in the first season (Table 7). **7. Grain yield (ardab fed⁻¹):**

The results in Table 8 indicate that grain yield fed⁻¹ of wheat significantly differed due to various studied cultivars (Sakha 95 "C₁" and Misr-3 "C₂") in the first sowing date in both seasons, but these differences in the second and third sowing dates in both seasons were insignificant. Where, C₁ cultivar surpassed other studied cultivar and resulted in the highest values of grain yield fed⁻¹ under three studied sowing dates in both seasons. While, C₂ cultivar recorded the lowest values of grain yield fed⁻¹ under three studied sowing dates in both

Egypt. J. Agron. **46,** No. 1 (2024)

seasons. These findings might be attributed to the differences in their genetical constitution and genetic factors makeup. These results are in conformity with those reported by Baqir and Al-Naqeeb (2018), Sayed *et al.* (2018), Gomaa *et al.* (2018), Hassanein *et al.* (2018) and Khan *et al.* (2019).

Increasing seeding rates from 30 to 50 and 70 kg grains fed⁻¹ associated with significant increase in grain yield fed⁻¹ under three studied sowing dates (Table 8). The highest values of grain yield fed⁻¹ produced from sowing with the highest seeding rate (70 kg grains fed⁻¹) under three studied sowing dates in both seasons. However, the lowest values of grain yield fed⁻¹ were obtained from sowing with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. The increase in grain per individual wheat plant due to the decrease in seeding rate may be due to the low competition among the adjacent plants, which led to increase the amount of solar radiations intercepted

by plants, as well as higher aeration and light distribution among plants, which led to increase the photosynthetic activities and dry matter accumulation per plant. But at the same time, wheat grain yield fed⁻¹ increased when sowing wheat with the highest seeding rate may be due to the increase in the No. of plants holder spikes per unit area. These results are in agreement with those obtained by Ahmad *et al.* (2018), Yang *et al.* (2019), Iqbal *et al.* (2020), Matsuyama and Ookawa (2020), Twizerimana *et al.* (2020) and Ghazanfar *et al.* (2023).

Data in Table 8 show that studied nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) had a significant effect on grain yield fed⁻¹ under three studied sowing dates in both seasons, except in the third sowing dates (sowing on 25th December) in the two growing seasons. It was observed that increasing nitrogen levels up to 100 kg N fed⁻¹ resulted in the

highest values of grain yield fed⁻¹ under three studied sowing dates in both seasons. In contrast, the lowest values of grain yield fed⁻¹ were resulted from application of 50 kg N fed⁻¹ under three studied sowing dates in both seasons. The increase in grain yield due to increasing nitrogen fertilizer levels up to 100 kg N fed⁻¹ can be easily ascribed to the nitrogen which consider as one of the major elements for plant nutrition and it increases the vegetative cover for plant and forms strong plants with long spikes. In addition, the low soil content of available nitrogen (Table 1) which compensated with application of nitrogen fertilization. Moreover, nitrogen encourages plant to uptake other elements consequently activating. enhancing growth measurements and all yield components and grain yield per unit area. These results are in good accordance with those of Liu et al. (2019), Yang et al. (2019) and Seadh et al. (2020).

 TABLE 8: Mean squares and mean performance of grain yield fed⁻¹ as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seesons

With respect to the interactions, the interaction between $C \times SR$ in 25th October sowing date in the first season had a significant effect on grain yield fed⁻¹, vice versa with regard to other interactions (Table 8).

8. Harvest index (HI):

As shown from data in Table 9, there were significant differences among studied cultivars (Sakha 95 "C₁" and Misr-3 "C₂") in harvest index (HI) in the first sowing date (25^{th} October "SD₁") in the first season and in the three sowing dates in both seasons. The highest values of HI were obtained from C₁ cultivar, which were 34.72, 34.30, 34.64, 34.66, 34.07 and 33.39 in the three sowing

dates in the first and the second seasons, respectively. The variation among wheat cultivars in HI may be due to the genetical variation among them. Comparable results were obtained by El-Sayed *et al.* (2018) and Gomaa *et al.* (2018).

Seeding rates of 30, 50 and 70 kg grains fed⁻¹ insignificantly affected harvest index (HI) under three studied sowing dates in both seasons, except the second sowing date (25^{th} November) in the two growing as shown from data in Table 9. Sowing wheat plants with the lowest seeding rate (30 kg grains fed⁻¹) resulted in the lowest values of HI under three studied sowing dates in both seasons. However, sowing wheat plants with the highest

seeding rate (70 kg grains fed⁻¹) resulted in the highest values of HI under three studied sowing dates in both seasons. Such increase in HI as a result of increasing seeding rate might be due to the

same reasons that mentioned and discussed formerly in increasing biological and grain yield fed⁻¹. These results are coincidence with those obtained by Ahmad *et al.* (2018).

TABLE 9: Mean squares and mean performance of harvest index (HI) as affected by cultivars, seeding
rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022
and 2022/2023 seasons.

CV	1.37	16.45	2.23	8.02	13.65	0.94	

Data listed in Table 9 show that nitrogen fertilizer levels markedly affected harvest index (HI) in the second sowing date (25^{th} November "SD₂") in the second season. Application of 100 kg N fed⁻¹ produced the highest values of HI under three studied sowing dates in both seasons. In contrast, the lowest values of HI under three studied sowing dates were resulted from application of 50 kg N fed⁻¹ in both seasons. Such increase in HI as a result of increasing nitrogen levels might be due to the same reasons that mentioned and discussed formerly in increasing biological and grain yield fed⁻¹.

With concern to the interactions, the interactions among studied factors on harvest index (HI) were insignificant under three studied sowing dates in both seasons (Table 9).

9. Crude protein percentage in grains (%):

Wheat cultivars under study (Sakha 95 " C_1 " and Misr-3 " C_2 ") were significantly differed in crude protein percentage under three studied sowing dates in both seasons, except the second sowing date (25th November) in the second season as shown in Table 10. C_1 cultivar surpassed other studied cultivar and resulted in the highest values of crude protein percentage under three studied sowing dates in both seasons. While, C_2 cultivar recorded the lowest values of crude protein percentage under three studied sowing dates in both seasons. These results are in agreement with those reported by El-Sayed *et al.* (2018).

Corresponding results listed in Table 10 which revealed that there was significant effect on crude protein percentage due to studied seeding rates (30, 50 and 70 kg grains fed⁻¹) under three studied sowing dates in both seasons. The highest values of crude protein percentage were recorded due to sow with the lowest seeding rate (30 kg grains fed⁻¹) under three studied sowing dates in both seasons. On opposition to, the lowest values of crude protein percentage were produced from sowing with the highest seeding rate (70 kg grains fed⁻¹) under three studied sowing dates in both seasons. These results may be due to the high competition between the adjacent plants at higher seeding rate for light, water and nutrients which led to decrease photosynthetic activities and produce less dry matter accumulated in different plant organs and decreasing crude protein percentage in wheat grains.

 TABLE 10: Mean squares and mean performance of crude protein percentage in wheat grains as affected by cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates during 2021/2022 and 2022/2023 seasons.

Concerning the effect of nitrogen fertilizer levels on crude protein percentage, the results indicated that crude protein percentage was significantly affected by nitrogen fertilizer levels (50, 75 and 100 kg N fed⁻¹) under three studied sowing dates in both seasons, except the third sowing date (25th December) in the second season (Table 10). Application of 100 kg N fed⁻¹ resulted in the highest values of crude protein percentage, while application of 50 kg N fed⁻¹ resulted in the lowest values of crude protein percentage under three studied sowing dates in both seasons. This increase in crude protein content in wheat grains due to increasing nitrogen fertilizer levels may be due to the role of nitrogen fertilizer in improving growth and dry matter accumulation as well as by the influence of nitrogen availability at critical stages of spike initiation and the development of plant metabolism, which leading to increase synthesis of amino acids and their incorporation into grain protein. These results are in good accordance with those of Ali et al. (2019).

Crude protein percentage was significantly affected by various interactions among studied factors *i.e.* cultivars, seeding rates and nitrogen fertilizer levels under the three studied sowing dates in both seasons, except the interaction between $C \times SR$ in the first sowing date in the first season and the interaction between $C \times N$ under the three studied sowing dates in both seasons (Table 10).

Conclusion

From the results of this study, it could be recommended that sowing wheat Sakha 95 cultivar

on 25th November with 50 kg grains fed⁻¹ and fertilizing with 100 kg N fed⁻¹ obtained the highest productivity and grains quality under the environmental conditions of Qalin City, Kafrelsheikh Governorate, Egypt.

استجابة إنتاجية وجودة حبوب بعض أصناف القمح لمعدلات التقاوى ومستويات التسميد النيتر وجينى تحت مواعيد زراعة مختلفة

عماد الدين أحمد أنور رشوان¹، وليد ذكي اليماني فرحات² و هاشم محمد عبد اللطيف³ ومحمد إبراهيم حسن الجندي¹ ¹ قسم المحاصيل، كلية الزراعة ، جامعة طنطا ، مصر . ² قسم بحوث القمح، معهد بحوث المحاصيل الحقلية، مركز البحوث الزراعية، مصر . ³ قسم المحاصيل، كلية الزراعة ، جامعة القاهرة ، مصر .

أجريت تجربتان حقليتان بحقل خاص بمدينة قلين، محافظة كفر الشيخ، مصر خلال الموسمين الشتوبين المتتاليين و2022/2021 و22023/2022 بهدف دراسة استجابة المحصول ومكوناته وجودة الحبوب لبعض أصناف القمح المصري الجديدة (سخا 95 ومصر 3) لمعدلات التقاوى (30، 50 و70 كجم تقاوى/فدان) ومستويات السماد النيتروجيني (50، 75 و2001 كجم نيتروجين/فدان) خلال مواعيد زراعة مختلفة (25 أكتوبر، 25 يوفمبر و25 ديسمبر) تحت الظروف البيئية لمدينة قلين، محافظة كفر الشيخ، مصر. تم إجراء كل موعد للزراعة في تجربة منفصلة (ثلاث تجارب). نفذت كل تجربة لمواعيد الزراعة في تصميم القطع المنشقة مرتين في أربعة مكررات. وأوضحت النتائج المتحصل عليها أن مواعيد الزراعة لمواعيد الزراعة في تصميم القطع المنشقة مرتين في أربعة مكررات. وأوضحت النتائج المتحصل عليها أن مواعيد الزراعة وأصناف القمح ومعدلات التقاوى ومستويات السماد النيتروجيني أثرت معنوياً في عدد السنابل/م2، طول السنبلة، عدد وأصناف القمح ومعدلات التقاوى ومستويات السماد النيتروجيني أثرت معنوياً في عدد السنابل/م2، طول السنبلة، عد وأصناف القمح ومعدلات التقاوى ومستويات الماد النيتروجيني أثرت معنوياً في عدد السنابل/م2، طول السنبلة، عدد وأصناف القمح ومعدلات التقاوى ومستويات الماد ما لنيتر وجيني أثرت معنوياً في عدد السنابل/م2، طول السنبلة، عدد ونسبة البروتين الخام في الحبوب/سنبلة، وزن 1000 حبة، المحصول البيولوجي/فدان، محصول الحبوب/فدان، دليل الحصاد ونسبة البروتين الخام في الحبوب في معظم الحالات. من النتائج المحصل عليها من هذه الدراسة يمكن التوصية بزراعة القمح صنف سخا 95 في 25 نوفمبر بمعدل تقاوى 50 كم تقاوى/فدان مع التسميد النيتروجيني بمعدل 100 كم منيتروجين/فدان
